## Editor's preface

The present publication entitled "Geothermal Map of Switzerland 1995 (Heat Flow Density)" is Report N° 30 of the "Contributions to the Geology of Switzerland - Geophysical Series" published by the Swiss Geophysical Commission.

It contains a short description of the data acquisition and processing used by the authors, a description of the measuring technique for the determination of rock thermal conductivity, the applied temperature corrections and finally the adopted mapping technique.

Several maps at large scale are also included in this booklet, which show for example temperatures at 500, 1000 and 2000 m depth.

Finally seven pages (Appendix I and II) present the heat flow data base of the available sites outside and inside Switzerland.

The Swiss Geophysical Commission is very grateful to Prof. Dr. Ladislaus Rybach and Dr. Fausto Medici for having taken the initiative in realizing this publication.

Special thanks are due to the Swiss Academy of Natural Sciences for its financial support of this publication.

Zürich, December 1995

In the Name of the  
Swiss Geophysical Commission  
The President:

Prof. E. Klingelé

## Preface

The geothermal map of Switzerland is No. 10 of a series of geophysical maps on the scale 1: 500'000. These maps aim at the representation of the main geophysical parameters and are being prepared and produced by the Swiss Geophysical Commission. The geothermal conditions in the subsurface of Switzerland are represented in the form of a heat flow density map. The terrestrial heat flow density at the surface is in fact closely related to the temperature field at depth.

The temperature distribution in the subsurface is, besides its scientific interest, of great importance for various fields of practical applications:

- for the construction of underground facilities (e.g. for storage or transportation)
- for the utilisation of groundwater resources
- for the exploration of hydrocarbons
- for the development and exploitation of geothermal energy
- for the disposal of radioactive and/or toxic wastes in geological formations

More than ten years have passed since the first edition of the Geothermal Map of Switzerland was published. In the meantime, numerous new heat flow density (HFD) determinations have approximately doubled the available database. The need of a revised edition of the geothermal map thus became evident.

The HFD map of Switzerland reflects the status of knowledge at the end of 1995. HFD determinations of neighbouring countries, incorporated now in the EGT catalogue, were also available. Nevertheless, in areas with few data points, new values that diverge from the local trends could change the isoline patterns considerably.

The HFD data density in Switzerland is among the highest in the world. Nevertheless, more HFD determinations, especially in the Alps, are needed to delineate more precisely the terrestrial heat flow pattern.

Most HFD determinations have been performed in objects available for measurements ("opportunity boreholes", tunnels or shafts). In this regard the co-operation of numerous builders, oil exploration companies, consulting bureaux and various cantonal and communal authorities must be mentioned.

## 1. Introduction

The geothermal conditions in the subsurface of Switzerland are represented in the form of a map of the terrestrial heat flow density on the scale 1 : 500'000. The map displays the lateral variation of the terrestrial heat flow density (HFD) near the earth's surface. The HFD [ $\text{mW m}^{-2}$ ] is the amount of heat flowing per unit time and area through the earth's surface from its interior. The HFD is closely related through the rock thermal conductivity to the subsurface temperature field. Reliable information about the subsurface temperature distribution is of growing importance today for a variety of tasks including the planning and construction of subsurface facilities for either storage or transportation (e.g. alpine transversal), the development and exploitation of geothermal energy, the utilisation of groundwater resources and the disposal of radioactive waste in geological formations. In addition to the HFD map, subsurface temperatures at 500, 1000 and 2000 m depth are represented by isoline maps.

The representation of HFD by isolines on a map requires a certain minimum of data density. The necessary database has become available in Switzerland only in the early eighties, despite of several pioneering achievements in geothermics made in this country a long time ago. Among these were the first reliable measurements of the geothermal gradient, performed in 1832 in a 220 m deep borehole at Pregny near Geneva. A value of  $0.034 \text{ }^{\circ}\text{C m}^{-1}$  (recalculated from Réaumur temperatures and "pieds royaux français" depths) was found (De la Rue and Marcket, 1834). Later the construction of the Gotthard railroad tunnel (1872-1882), a pioneering engineering venture at that time, gave impetus to a number of basic contributions in geothermics:

- systematic measurements of rock temperatures (Stapff, 1887)
- the first HFD estimate for continental Europe ( $77 \text{ mW m}^{-2}$ , Stapff, 1883)
- the first method for topographic correction to the temperature gradient (Königsberger and Thoma, 1906)
- the first reported correlation of heat flow with local rock radioactivity (Joly, 1909).

Modern HFD determinations in Switzerland began with the investigations of Clark and Niblett (1956), who evaluated the data from the railroad tunnels in the Swiss Alps (Gotthard, Simplon, Lötschberg). Further heat flow determinations have been carried out more recently in boreholes, shafts and in lake bottom sediments. The effect of uplift/erosion on surface heat flow in the Alps was recognised and discussed by Clark and Jäger (1969). An attempt to obtain characteristic thermal properties of Swiss rocks was made by Wenk and Wenk (1969). In 1979 only nine HFD values had been reported in Switzerland. In the early eighties concentrated efforts of both the Swiss Geophysical Commission and the Swiss Federal Commission for the Utilisation of Geothermal Energy and Underground Heat Storage resulted in numerous new HFD determinations. At that time about 150 HFD values were available for the drawing up of a Swiss geothermal map. Since then more data are become available. The database consists nowadays of about 340 HFD determination; 150 in Switzerland and 190 in the surroundings.

The HFD has been calculated as the product of the geothermal gradient ( $dT/dz$ ) and the rock thermal conductivity K. In doing so, steady state, one dimensional conductive heat transfer was assumed. Measurements sites were omitted if the gradient was highly disturbed by moving groundwater. Both K and  $dT/dz$  can vary with locality. K depends on the mineralogical composition and on the petrophysical properties of the rocks. Because in most cases no rock cores from the boreholes were available, a thermal conductivity catalogue of the main Swiss rock types was established on the basis of laboratory measurements. At present about 550 samples have undergone a K determination. For most of the boreholes the thermal conductivity profile was obtained using this catalogue and their lithological profiles. The Bullard-plot technique was then used to calculate the HFD.

However, before calculating the HFD, corrections were applied to the temperature data. In addition to corrections for thermal disturbance caused by drilling fluid circulating within the borehole, several other corrections related to conditions at the earth's surface were performed. These included corrections for paleoclimatic temperature fluctuations and for the topographic relief. Computer codes have been developed to perform all the necessary calculations. For the HFD map at 1 : 500'000 only the topographic correction was applied according to common practice. The Swiss HFD map is therefore compatible with the HFD maps of other European countries.

The contouring of isolines at  $10 \text{ mW m}^{-2}$  intervals was done by computer with some final manual corrections. The geographical distribution of the data points used for contouring is highly uneven, being

largely based on opportunity objects such as exploratory or commercial boreholes available for  $dT/dz$  determinations. Since many original data from boreholes are not more directly available and since from most foreign data very little is known, is not possible to check the quality and the uncertainty of every HFD determination. In general the quality of HFD determinations from shallow boreholes (< 200 m depth) is quite poor.

The surface HFD is a complex signal comprising long and short wavelength components. The first ones are due to regional variations of deep HFD (crustal and lithospheric), the second ones to shallower local HFD changes. In Switzerland the mean regional HFD decreases towards the south, from the Jura to the Central Alps and increases slightly south of the Central Alps. Several superimposed local anomalies can be attributed to deep groundwater circulating systems.

Although the density of HFD determinations in Switzerland is one of the highest in Europe, periodic updating on the basis of new data will be indispensable.

## 2. Zusammenfassung

Die geothermischen Verhältnisse im Untergrund der Schweiz werden in Form einer Wärmestromdichte-karte im Massstab 1 : 500'000 dargestellt. Diese Karte zeigt die lateralen Änderungen der terrestrischen Wärmestromdichte in der Nähe der Erdoberfläche. Die Wärmestromdichte, "heat flow density" (HFD [ $\text{mW m}^{-2}$ ]), ist die aus dem Erdinnern stammende Wärmemenge, welche pro Zeit- und Flächeneinheit die Erdoberfläche durchströmt. Die HFD wird von der Gesteinswärmefähigkeit und vom Temperaturfeld des Untergrundes bestimmt. Zuverlässige Angaben über die Temperaturverhältnisse im Untergrund sind heutzutage für mehrere Projekte von wachsender Bedeutung. Dabei sind gemeint: die Planung und Herstellung von Untergrundeinrichtungen für Lagerung oder Transport (z.B. NEAT-Projekt), die Entwicklung und Nutzung von geothermischer Energie, die Nutzung von Grundwasserressourcen und dieendlagerung von radioaktiven Abfällen in geologischen Formationen. Zusätzlich zur HFD-Karte sind die Temperaturen im Untergrund in 500, 1000 und 2000 m auf Karten gegeben.

Die Darstellung von HFD-Werten mittels einer Isolinienkarte erfordert ein Minimum an Datendichte. Die dafür notwendige Datenmenge stand erst Anfang der achtziger Jahren zur Verfügung; dies trotz einiger Pionierarbeiten in der Geothermie, welche in der Schweiz vor vielen Jahren geleistet wurden. Unter diesen sind zu erwähnen die ersten zuverlässigen Messungen des geothermalen Gradienten, durchgeführt 1832 in einem 220 m tiefen Bohrloch in Pregny bei Genf. Es wurde ein Wert von  $0.034 \text{ }^{\circ}\text{C m}^{-1}$  (nachgerechnet aus Temperaturen in Réaumur und Tiefen in "pieds royaux français") gefunden (De la Rue and Marcet, 1834). Später führte der Bau des Gotthardseisenbahntunnels, zu dieser Zeit eine Pionierunternehmung des Ingenieurwesens, zu zahlreichen grundlegenden Beiträgen in der Geothermie:

- systematische Messungen von Felstemperaturen (Stapff, 1887)
- die erste Schätzung der HFD für das kontinentale Europa ( $77 \text{ mW m}^{-2}$ , Stapff, 1883)
- die erste Methode zur topographischen Korrektur des geothermischen Gradienten (Königsberger and Thoma, 1906)
- die ersten publizierten Zusammenhänge zwischen Wärmefluss und lokaler Gesteinsradioaktivität (Joly, 1909).

Moderne HFD-Bestimmungen begannen in der Schweiz mit den Untersuchungen von Clark und Niblett (1956), welche die Daten aus den Eisenbahntunnels in den Schweizer Alpen (Gotthard, Simplon, Lötschberg) bewerteten. Zusätzliche HFD-Bestimmungen wurden aus Bohrlöchern, Stollen und in Sedimenten am Seegrund gewonnen. Der Effekt von Hebung/Erosion auf dem Wärmefluss in den Alpen wurde von Clark und Jäger (1969) erkannt und diskutiert. Ein Versuch, thermische Eigenschaften von Schweizer Gesteinen zu bestimmen, wurde von Wenk und Wenk (1969) durchgeführt. 1979 waren in der Schweiz nur neun HFD-Werte bekannt. Anfang der achtziger Jahre führten gemeinsame Bemühungen der Schweizerischen Geophysikalischen Kommission und der Eidgenössischen Fachkommission für die Nutzung geothermischer Energie und die unterirdische Wärmespeicherung zur Bestimmung zahlreicher neuer HFD-Daten. Zu dieser Zeit standen etwa 150 HFD-Werte für die Erstellung der geothermischen Karte der Schweiz zur Verfügung. Seither sind mehrere neue HFD-Daten errechnet worden. Die aktuelle Datenbank enthält etwa 340 HFD-Bestimmungen, davon 150 in der Schweiz und 190 im angrenzenden Ausland.

Die HFD wurde als Produkt des geothermischen Gradienten ( $dT/dz$ ) und der Gesteinswärmefähigkeit  $K$  berechnet, d.h. unter Annahme von stationärem und eindimensionalem konduktivem Wärmetransport. In Fällen, wo der geothermische Gradient sehr stark von fließendem Grundwasser beeinflusst war, wurden die Messdaten nicht berücksichtigt. Beide,  $K$  und  $dT/dz$ , können je nach Lokalität variieren.  $K$  ist von der mineralogischen Zusammensetzung und von den petrophysikalischen Eigenschaften der Gesteine abhängig. Da in den meisten Fällen keine Bohrkerne von den Bohrungen, in welchen die Temperatur gemessen wurde, zur Verfügung standen, wurde ein Wärmeleitfähigkeitskatalog von schweizerischen Gesteinen anhand von Labormessungen erstellt. Zur Zeit enthält dieser Katalog  $K$ -Werte von etwa 550 Gesteinsproben. Bei den meisten Bohrlöchern wurden die Wärmeleitfähigkeitsprofile anhand dieses Kataloges und des lithologischen Bohrlochprofils erstellt. Für die Berechnung der HFD-Werte wurde die Bullard-plot Methode benutzt.

Bevor die HFD-Werte berechnet wurden, mussten die Temperaturdaten jedoch korrigiert werden. Zusätzlich zu den Korrekturen für die thermische Störung, verursacht durch die Spülflüssigkeit im Bohrloch, wurden andere Anpassungen der Temperaturdaten betreffend die Bedingungen an der

Erdoberfläche wurden durchgeführt. Diese beinhalten Korrekturen für die paläoklimatischen Temperaturschwankungen und für das topographische Relief. Computerprogramme wurden für die Durchführung aller notwendigen Berechnungen entwickelt. Für die HFD-Karte 1:500'000 wurden üblicherweise nur die topographischkorrigierten HFD-Werte benutzt. Die schweizerische HFD-Karte ist somit mit denjenigen anderer Länder völlig kompatibel.

Die Isoliniendarstellung der Karte in Intervallen von  $10 \text{ mW m}^{-2}$  wurde vom Computer errechnet. Kleine Abänderungen wurden anschliessend manuell durchgeführt. Die geographische Verteilung der Datenpunkten ist sehr unregelmässig, weil diese an "Gelegenheitsobjekte", wie Explorations- oder Nutzbohrungen, verfügbar für  $dT/dz$ -Bestimmungen, gebunden sind. Da die meisten Originaldaten von den Bohrungen nicht mehr direkt verfügbar sind und da über ausländische Daten sehr wenig bekannt ist, war es nicht möglich die Qualität und die Genauigkeit der HFD-Werte zu berücksichtigen. Generell ist die Qualität der HFD-Werte aus untiefen Bohrungen ( $<200 \text{ m}$ ) ziemlich schlecht.

Das an der Erdoberfläche beobachtete HFD-Signal ist die Summe lang- und kurzwelliger Komponenten. Die ersten werden von regionalen Änderungen der HFD tief in der Erdkruste und in der Lithosphäre verursacht, die zweiten von lokalen untiefen Variationen der HFD. In der Schweiz nimmt die mittlere regionale HFD südwärts ab, vom Jura bis zu den Zentralalpen, und nimmt südlich der Zentralalpen wieder leicht zu. Einige überlagerte lokale Anomalien werden wahrscheinlich von tiefen Grundwasserkirculationssystemen verursacht. Obwohl die Dichte der HFD-Bestimmungen in der Schweiz eine der grössten in Europa ist, sind periodische Neubearbeitungen der geothermischen Karte anhand neuerer Daten unerlässlich.

### 3. Geological background

A brief overview of the main geologic-tectonic units in Switzerland is given below. For more detailed information see e.g. Trümpy (1980), Müller et al. (1984), Diebold et al. (1991).

The area of Switzerland can be geologically subdivided from north to south into the following main units: Rhine Graben, Tabular (Plateau) Jura, Folded Jura, Molasse Basin and the Alps. The latter is further subdivided into: Helvetic belt, Alpine massifs and their autochthonous and paraautochthonous sedimentary covers, Penninic units, Austroalpine nappes and, south to the Insubric line, the Southern Alps, reaching into the Tertiary Molasse of the Po plain. These simplified and integrative units are indicated (in German) on the geothermal Map of Switzerland. A more detailed geological map is shown on Fig. 2 (simplified from Trümpy, 1980); the following short description of its main geological units is based on Trümpy (1980) and Bodmer and Rybach (1984).

#### 2.1 Rhine Graben (RG)

In the northern foreland of the Alps, the Variscan crystalline basement rocks ("Moldanubian"), visible at the surface in the Black Forest (SC) and Vosges (VO) massifs, dip gently southwards where they are overlain by an autochthonous sedimentary cover. The massifs are separated by the Rhine Graben, a continental rift structure which has its southern end, at least at the surface, near the Swiss border in the area of Basel. Although the main rifting phase dates back to the late Eocene, different parts of the Graben area have been active since then. Shear movements are predominant in recent times. Due to its high degree of fracturing at depth and the corresponding possibilities for vertical water circulation, the Rhine Graben area and especially its rim zones are of considerable geothermal interest (Rybach, 1981; Gürler et al., 1987; Hauber, 1993). The graben fill consists of Tertiary (Molasse) and some Quaternary sediments.

#### 2.2 Tabular Jura (TJ)

The subhorizontal Mesozoic cover rocks lying unconformably on the buried southern extension of the Vosges/Black Forest crystalline basement consist, except for some Tertiary remnants, of a more or less continuous sedimentary sequence of age between the Lower Trias and the Upper Malm. Below this cover, older sediments are embedded at places into the basement in trough and graben structures. In the Permocarboniferous trough of northern Switzerland beneath the Tabular Jura, two superimposed troughs exist (in total 5 km thick, Diebold et al., 1991): an older, lower trough filled with Stephanian to Lower Permian sediments with coal measures, and an upper, younger trough filled with Upper Permian redbeds.

Especially near the Rhine Graben the Tabular Jura is cross-cut by a dense and complex fault system with a preferred N-S orientation. Most of these faults are of Oligocene age, although there is evidence for movements in both the Trias (NEFF, 1980) and in the Quaternary (Herzog, 1956).

#### 2.3 Folded Jura (FJ)

South of a major thrust zone lies the Folded Jura, consisting of the same cover as the Tabular Jura rocks (in Western Switzerland also of Cretaceous age), but decoupled from the basement and transported northwards for about 2 km in its eastern part and for 25 to 30 km in its western part. This thin-skinned detachment tectonics led to the formation of Jura-type thrust-and-fold structures. The thrust horizon is located within a relatively soft evaporite sequence of Middle Trias age ("Anhydrit Gruppe"). The sediments below the thrust are supposed to be directly connected to the Tabular Jura and are considered autochthonous. The crustal shortening has most probably also affected the crystalline basement. The foreland basement with its Tabular Jura-type cover (plus further Permocarboniferous troughs) dips gently ( $2^{\circ}$ - $3^{\circ}$ ) in SSE direction beneath the Molasse basin, forming the fundament of that structural unit, and extending well below the northward thrusted external crystalline massifs of the Alps.

#### 2.4 Molasse basin (MO)

The Molasse basin is a deep (up to 6 km), elongated, asymmetric trough between the Jura and the Alps filled with Oligocene and Neogene detrital sediments of Alpine origin. Lithologies vary from calcareous shales and sandstones to coarse conglomerates with marked coarsening and thickening from north to south, i.e. from the distal to the proximal parts of the basin.

The southern part of the basin shows complex relationships between sedimentation and tectonics. Northward thrusting folded and deformed this part of the Molasse basin. The coarse synorogenic clastic sediments were subsequently overridden by nappes from the south and transformed into a deformed wedge (Subalpine Molasse, SM).

## 2.5 The Alps

The Alps form the complex collision zone between the European and African plates. The numerous tectonic units of the Alps can only very briefly be mentioned here:

- the *Prealpes* (PR), décollements nappes of Mesozoic and Paleogene terranes, derived from the Ultrahelvetic zone and from various parts of the Penninic belt, found near the outer margin of the Alps between Lake Annecy and the Linth valley. They overlay Helvetic nappes or come to rest directly upon the Subalpine Molasse.
- the *Helvetic belt* (HE), the autochthonous and parautochthonous zones, and further the northwards thrusted Helvetic and Ultrahelvetic nappes, dominated by Cretaceous limestones, originally located between the southern rim of the Aar massif and the north Penninic domain (Masson, in Trümpy, 1980)
- the *Alpine (Central) massifs*, comprising the "external" massifs, Aiguilles Rouges (AG), Mont Blanc (MM) and Aar (AM), and the "inner" massifs, Gotthard (GM) and Tavetsch. They mainly consist of granites, gneisses and schists, and were deformed, metamorphosed and partly also thrusted during the Hercynian orogeny and again during the Alpine event.
- the *lower* (PB) and *upper* (PM) *Penninic*, the *lower* (AS) and *upper* (AB) *Austroalpine units*, a complicated sequence of different rock types of Permian to Mesozoic age: sedimentary, volcanic (ophiolites) and metamorphic rocks also of basement type. They show imbricated structures and they were thrusted northward during the Alpine orogeny. The degree of metamorphism in these units generally increases from north to south, where they dip into a steep zone, which is now interpreted as backfold (Pfiffner, 1992).
- the *Southern Alps*, clearly separated from the rest of the Alps by a major tectonic lineament, the Insubric line (IL), including the Ivrea zone with ultrabasites and granulite facies metamorphic rocks of possibly Variscan lower crust/upper mantle origin. In the north, crystalline basement units (BS) show a considerably lower degree of metamorphism, from greenschist to amphibolite facies, than immediately north of the Insubric line. Further to the south, Mesozoic and Paleozoic sediments (SA) and thick Permian volcanic rocks lie on this "Adriatic" basement. The sedimentary units are derived from the same facies belt as the Autoalpine nappes.

Directly adjacent to the Insubric line lie the Bergell (BE) and the Adamello (AD), both granitoid intrusions of Tertiary age. The southernmost tip of Switzerland reaches into the Tertiary basin of the Po plain (Molasse of Como).

## 4. Database

Since the first edition of the Geothermal Map of Switzerland (Bodmer and Rybach), 1984 many more temperature data from borehole and tunnels have been acquired both in Switzerland and in the neighbouring countries. Therefore the necessity for reviewing this map became necessary. Several authors have contributed to increase and improve the HFD database for Switzerland since 1983: Trabattoni (1986), Schärli (1989), Kälin and Rybach (1990) and Eugster (1993). In addition to these works a HFD data compilation in the context of the EGT project was prepared by Cermák (EGT catalogue). Since the reference sources for the HFD values are various, in many cases it was not possible to infer exactly about the correction procedures used. Therefore the knowledge, especially for foreign data, about the quality and the uncertainty of the HFD determination is quite poor. Sometimes data for a particular site differed between compilations and source references. This fact can be explained in some cases by a misinterpretation of the correction methods used in compiling a data set. The data of few sites in Switzerland were elaborated more than once; either for particular studies or because of numerical technique improvements. This led now and then to different HFD values for the same site. Usually the more recent data were retained, but the choice was not always based on well defined criteria. The database used for the compilation of the Geothermal Map of Switzerland is given in Appendix I and II. Appendix II contains more detailed information only because of the availability of more complete data from boreholes. For HFD determinations outside Switzerland only the sites situated up to a distance of ca. 50 km from each Swiss border extremities were used (i.e. inside Swiss co-ordinates 430.000/10.000 and 890.000/350.000, see Figure 2).

In the EGT catalogue only the co-ordinates of the sites and the values of  $Q_0$  (HFD determination without temperature correction, see chapter 5) and  $Q_c$  (HFD determination with temperature correction) are listed. Most probably the  $Q_c$  values in this catalogue are based on topographic corrected temperature data.

The HFD database consists nowadays of about 340 HFD determinations; 150 in Switzerland and 190 in the surroundings. Table 1 characterizes the HFD sites in Switzerland according to their category.

**Table 1** HFD site categories in Switzerland.

| Category of HFD determination | Number of HFD determinations |
|-------------------------------|------------------------------|
| Borehole                      | 108                          |
| Lake (11 different lakes)     | 40+2 *                       |
| Tunnel or shaft               | 14                           |

\* Also datapoints in foreign countries if the lake is partly situated in Switzerland. In the Lake of Constance in two locations two different temperature profile were measured

## 5. Data acquisition and processing

### 5.1 Heat flow density determination

The heat production within the earth is largely due to the radioactive decay of unstable natural isotopes, mainly  $^{238}\text{U}$ ,  $^{235}\text{U}$  and  $^{40}\text{K}$ . The increase of temperature with depth gives rise to a steady terrestrial heat flow which has a world-wide average value of  $87 \text{ mW m}^{-2}$  at the earth's surface (Pollack et al., 1993). The temperature increase with depth, called the geothermal gradient, reaches on the continents a value of approximately  $0.03 \text{ }^{\circ}\text{C m}^{-1}$  in the upper few kilometres of the earth's crust. The radioactive isotopes, responsible for most of heat generation within the earth, are mainly concentrated in the upper continental crust. In consequence, both the geothermal gradient and the terrestrial heat flow decrease continuously with depth.

The most significant heat transfer mechanisms in the subsurface are conduction and convection. The convection within the upper crust is very often related to water circulation through rock pores or fractures. In general, due to the poor knowledge of the hydrogeological conditions of the subsurface, it is not possible to calculate the part of heat transferred by convection.

The heat flow density  $q$  (HFD), due to the conductive process, is defined as the heat flow per unit area [ $\text{W m}^{-2}$ ] and is determined as follows:

$$q = K \nabla T \equiv K \frac{dT}{dz} \quad \text{where} \quad K = \text{rock thermal conductivity} [\text{W m}^{-1} \text{ }^{\circ}\text{K}^{-1}]$$
$$\frac{dT}{dz} = \text{geothermal gradient} [\text{ }^{\circ}\text{K m}^{-1}]$$

This formula can be derived from the general heat transport equation under simplified conditions (e.g. one dimensional flow, stationary conditions, etc.). When the HFD proves to be constant by the measurements, the assumption of pure conductive heat transfer is justified.

Since in many cases the convective heat transfer is much more effective than the conductive one, the detection of water circulation systems is possible. In fact they create strong local, horizontal and/or vertical variation of the temperature field and of the HFD, especially in and near discharge or recharge areas.

The terrestrial heat flow density cannot be measured directly at a specific point. It has to be determined, as the above formula suggests, using a temperature profile over a relatively large distance (i.e. deep boreholes). The temperature gradient in conjunction with the rock thermal conductivity along the measured distance will provide a value for the average HFD across the section investigated. For the computation of HFD only conductive heat transfer along the measured section (boreholes, tunnels, etc.) is assumed.

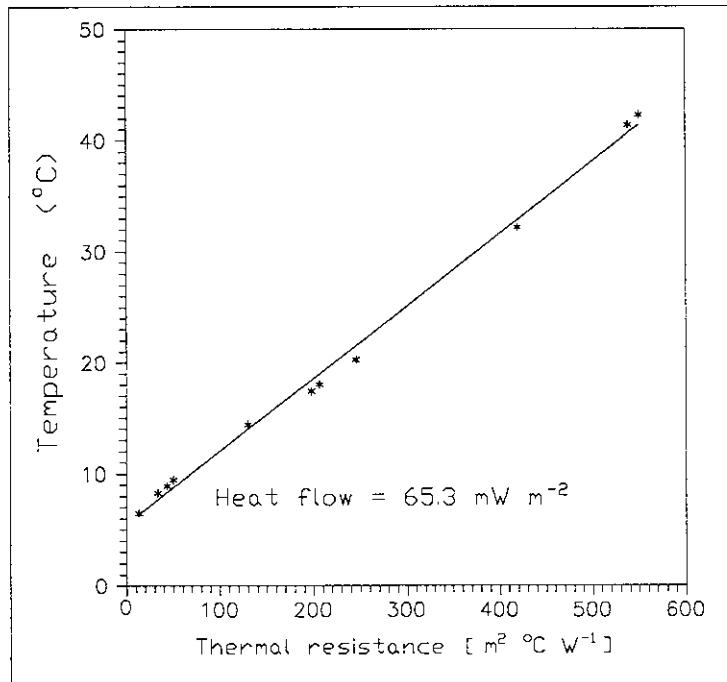

If important radioactive heat production occurs within the measured profile, this effect has to be taken in consideration as well.

The numerical processing of the above mentioned formula for calculating the HFD can be performed in different ways (see Rybach and Bodmer, 1983). The choice of the most suitable technique depends on the quality and sampling rate of both the temperature and the thermal conductivity data.

For HFD determinations in Switzerland, the "Bullard plot" technique (Bullard, 1939) was selected as the most reliable and useful one. Each temperature value is plotted versus the thermal resistance between the earth's surface and the depth of the temperature measurement (see Figure 3). The slope of the regression line is proportional to the HFD. This method provides good results, especially in deep boreholes where the data quality usually decreases with depth. Furthermore, this calculation method can be applied to all data categories.

Experience in interpreting heat flow data in specific areas has shown that in many cases the changes in temperature gradient with depth are not only due to variations in thermal conductivity, but are the result of various effects like water circulation, thermal disequilibrium during the measurements,

incomplete corrections, measurements errors, etc. A statistical approach to evaluate the heat flow density is therefore considered to be much more realistic than conventional techniques. Furthermore much useful information can be derived from the regression technique; e.g. the correlation coefficient for the evaluation of the input data quality and the statistical error of the regression slope, which gives a measure of the quality of the HFD determination. Also the results of regressions of higher orders can give information about possible water circulation.

## 5.2 Rock thermal conductivity

### 5.2.1 Measuring technique

The thermal conductivity measurements were carried out with a QTM™ apparatus. With this instrument, based on a transient measuring technique, a line heat source in a probe is gently pressed against a planar surface of the sample and is heated at a constant rate. The increase of temperature at the centre of this source is measured by a thermocouple and allows the direct determination of the thermal conductivity of the rock sample. The accuracy of the thermal conductivity measurement is approx.  $\pm 5\%$ , the reproducibility  $\pm 2\%$ , depending also on the homogeneity of the sample. It is also possible to carry out measurements on water saturated samples. The thermal conductivity data obtained with this technique is representative only for a small rock volume around the thermo-element. In order to avoid systematic errors due to the effect of rock inhomogeneities the measurement has to be repeated at many different locations on the sample. Both the measuring device and the technique are described in detail in Schärli (1980).

For the determination of the thermal conductivity anisotropy the measuring plane of the rock sample has to be cut perpendicularly to the layering or to the schistosity. The thermal conductivity parallel to the layering ( $K_p$ ) can be determined directly by positioning the line heat source on the sample perpendicularly to this direction. With a second measurement, holding the line heat source parallel to the layering, the component  $K_{gs}$  is obtained. The component perpendicular to the layers ( $K_v$ ) can then be calculated as follows:

$$K_v = (K_{gs})^2 / K_p \text{ (see also Grubbe et al., 1983).}$$

In case of horizontal layering the information concerning  $K_v$  is in general more important than of  $K_p$ , because it corresponds to the vertical component of the thermal conductivity, which determines the terrestrial heat flow. The conductivity anisotropy  $A$  is defined as the ratio  $K_p/K_v$ .

The thermal conductivity is also a function of temperature and pressure, which means that the values obtained at laboratory condition are slightly different from the real ones. Even if this is not a common practice sometimes this effect is taken in account for deeper boreholes (see e.g. Kälin and Rybach, 1990).

### 5.2.2 K determination on rocks: Results

From most boreholes selected for HFD determinations no core samples were available for thermal conductivity measurements. For this reason, appropriate surface rocks were sampled in order to obtain a representative conductivity profile across the geological sections found in the boreholes and also to establish a comprehensive thermal conductivity catalogue of Swiss rocks (Schärli, 1980; Bodmer and Schärli, 1983; Schärli, 1989). The actual catalogue consists of about 550 thermal conductivity determinations (status at the end of 1995). Most of the rock samples investigated have undergone also measurements to determine other physical properties such as porosity, density, radioactivity, etc. (Schärli, 1989).

Since the collected rock samples were not stored with special precautions their pore fluid evaporated almost totally. Therefore the samples had to be water saturated prior measuring. Except for rocks with very high porosity and permeability, it is recommended to evacuate the pore volume before the samples are watered. The other possibility is to put the samples in water for several days before measuring. Each rock sample had undergone 5 to 30 single measurements and from these an average value was calculated. The number of measurements taken was dependent on the degree of homogeneity of the rock material investigated.

The thermal conductivity of a rock is strongly dependent on its porosity, on the shape of its pores and the pore filling. In many cases these effects are even more important than the mineralogical composition of the sample. In fact the thermal conductivity of water is approximately twenty time larger than that of air. For this reason the thermal conductivity of water saturated samples is higher than that of the same dry samples, even at very small porosities (Schärli and Rybach, 1984). A general dependency of thermal conductivity on the porosity was proposed by Walsh and Decker (1966). Even at rock porosities below one percent, such as in crystalline rocks, this dependency is not negligible. Hanshin and Shtrikmann (1962) proposed theoretical relations for rocks with low porosities according to the shape of their pores.

For only a few HFD sites the vertical distribution of the thermal conductivity was measured in conjunction with the temperature log. In most cases the thermal conductivity information was extrapolated from other boreholes or from corresponding rock material sampled at the surface. Using the thermal conductivity catalogue the thermal conductivities were averaged by formation and attributed to the geological sections covered by the temperature measurements.

The knowledge of the anisotropy permits the selection of the thermal conductivity component parallel to the heat flow. In most HFD sites no exact information about the dip of the layering was available, such that horizontal layering had to be assumed. The error due to this assumption is negligible in most areas in the northern foreland of Switzerland. However in the Alps and in the Folded Jura this assumption is not valid and the dip of the layering has to be estimated from direct measurements in the field or at least from general trends in geological maps.

## 5.3 Temperature data categories

Numerous temperature data are available in Switzerland, mainly from boreholes in the northern foreland or from tunnels and shafts in the Alps. The quality of these data varies considerably. It is therefore necessary to eliminate unreliable data before further processing is possible. The different categories of temperature data used for HFD determinations are discussed below.

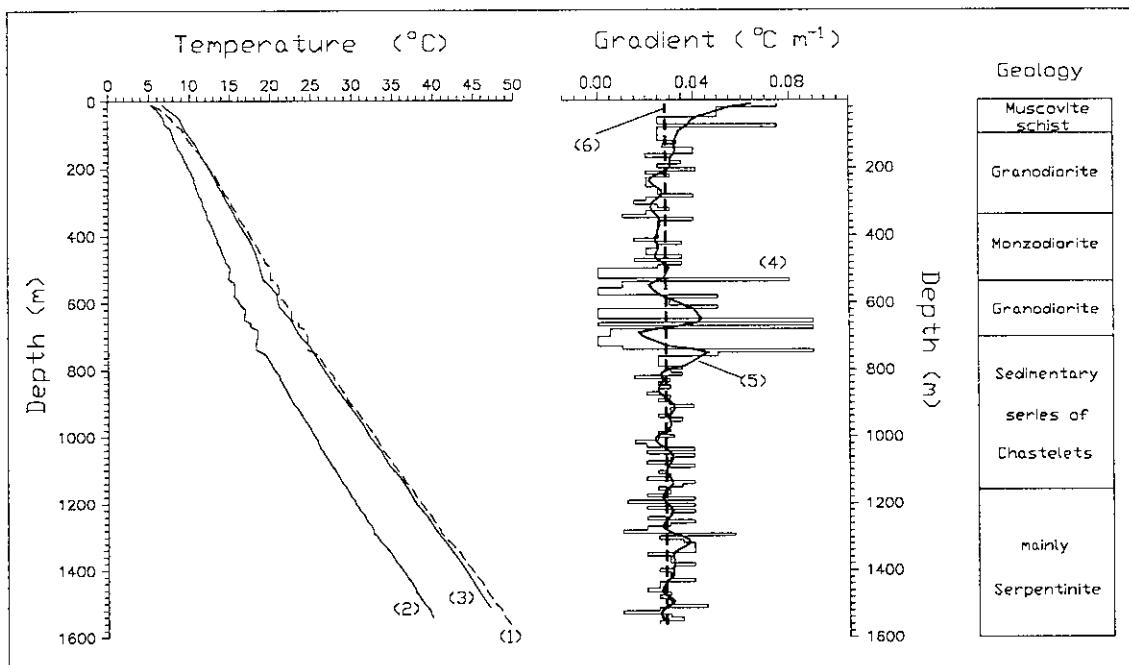

### 5.3.1 Temperature logs

The temperature logs are often the most reliable data due to the density of measuring points, to the knowledge of the borehole conditions and to the usually well calibrated measuring tools. Many temperature logs were performed by the Institute of Geophysics (ETH-Zürich).

If the measurements take place long enough after the last borehole disturbance, the fluid within it reaches an equilibrium temperature with its surroundings. The measured temperature will then correspond to the true rock formation temperature.

The shape of both temperature and differential temperature-depth profiles give information about the occurrence of water circulation in the vicinity of the borehole. An example is given in Figure 4: between 500 m and 750 m several water inflow zones are evident. The disturbance effect of inflowing water can be seen much more clearly in the gradient profile than in the temperature log. Especially where water movement is not parallel to the isotherms, heat transport due to convection is usually much more efficient than pure heat conduction. The identification of such convection zones is of primary interest in geothermal exploration.

Except for the Quaternary layers and a few local disturbances the temperature-depth profiles in the Tertiary sediments of the Molasse basin are nearly linear. However many local and regional temperature disturbances due to water or gas movement can be detected within the Mesozoic sediments in the Molasse basin and along the Jura.

**Figure 4.** Temperature log and Gradient plot of borehole St. Moritz. 1) unprocessed data. 2) for topography effect corrected temperature, 3) for topography and paleoclimate effects corrected temperature data. 4) unsmoothed gradient. 5) moving average over 5 intervals 6) average along the whole profile ( $0.0271\text{ }^{\circ}\text{C m}^{-1}$ ). For the gradient plot the unprocessed temperature data were used. 1 Interval = 5 m.

### 5.3.2 Individual temperature values

Many individual temperature values from boreholes, tunnels and shafts have been published or documented in internal reports. A few data from formation tests are also available. The quality of the data varies according to the measuring technique used. In tunnels and shafts it is important to obtain data shortly after the construction operations since air circulation due to ventilation affects strongly the rock temperature. Compared to the temperature logs this category of data is much less reliable because of instrumental imprecisions (e.g. calibration) and hydrogeological or other unknown disturbances. Many doubtful measurements have been eliminated, nonetheless this category of data should be considered with caution.

Usually the general trend of the temperature-depth curves is non linear due to variations in thermal conductivity with depth, to water convection and to the thermal history of the subsurface. Temperature

estimates between widely spaced measurement points should therefore not be evaluated by linear interpolation. A reasonable estimate of temperatures within lacking sections can be found by the use of master curves (Stegena, 1976). These curves are constructed on the basis of the best measured data within the area and are supposed to be representative for the regional geothermal field. For a typical set of curves for Switzerland see Synthese (1982). Such estimations should not be used for detailed calculations, because they do not take in account temperature gradient changes due to local conductivity variations or water movement.

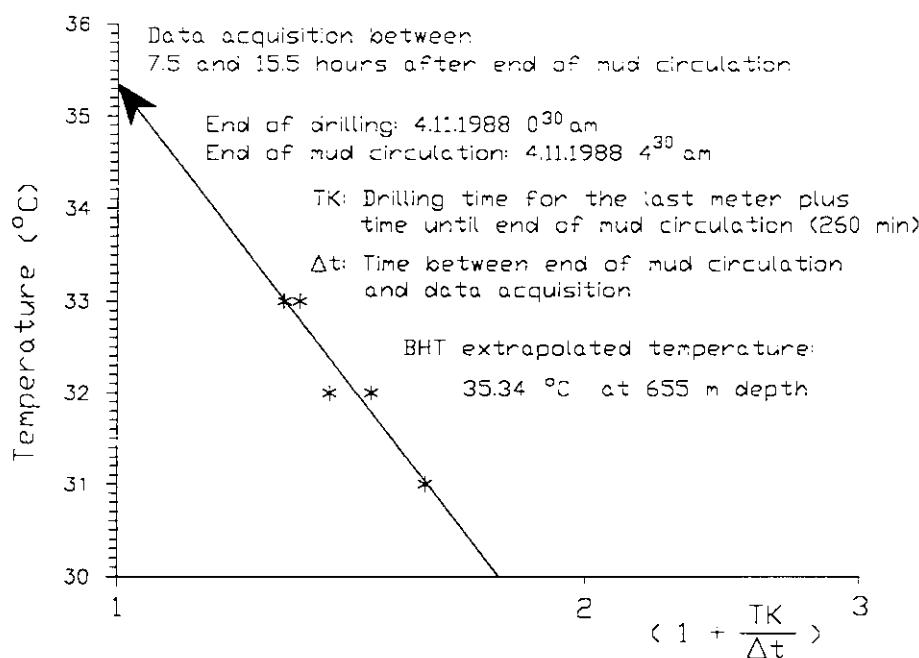

### 5.3.3 Bottom hole temperatures (BHT)

During borehole logging operations in deep boreholes maximum thermometers are usually carried along with the different logging tools. The maximum temperature obtained is generally considered to be the "bottom hole temperature" (BHT), since in most cases the temperature increases with depth. Because the measurements are usually performed a short time after the end of mud circulation in the borehole, these BHT values do not represent the true formation temperature. In fact, due to the high rig costs or to borehole exploitation, it is quite uncommon to perform BHT measurements after thermal equilibrium has been attained in the borehole. A correction method for disturbed BHT values was proposed by Lachenbruch and Brewer (1959). This method has been applied successfully in many cases, especially because the input parameters for the correction can usually be reconstructed from the drilling reports.

When the following two conditions take place the BHT temperature correction mentioned above is not anymore appropriate:

- a) the measured temperatures do not plot along a straight line after short equilibrium times
- b) using powerful drilling equipment, the mud temperature is often increased due to frictional effects. At shallow depths (< 500 m), the measured mud temperature is often higher than the formation temperature. Since the location of the maximum temperature measured in the borehole is no longer a function of the geothermal conditions, but of the drilling history, the quality of the corrected data is strongly affected.

In both cases more sophisticated correction methods are required for the evaluation of the true formation temperature.

**Figure 5.**  
BHT correction method.  
Borehole Kreuzlingen 2.

### 5.4 Temperature corrections

Depending on the purpose of geothermal mapping, different temperature corrections have to be applied to the measured data prior to the HFD determination. The corrections are of special importance in cases where the geothermal information has to be extrapolated in horizontal or vertical direction. The most common corrections are the ones eliminating the effects of topography, paleoclimatic variations, uplift/erosion and subsidence/sedimentation. The topographic correction is a static correction which

should be applied in any case, the other corrections however are only required for special applications of geothermal data.

Many different correction procedures have been published in the last decades. The desire to apply the most suitable correction technique to the given regional geothermal conditions is often in contradiction with a standardised format which enables the construction of maps on a continental or on a world-wide scale. First attempts to establish standard procedures in geothermics have been made by the International Heat Flow Commission and by the Commission of the European Communities (Haenel, Rybach and Stegema, 1988; Balling et al., 1981).

The different corrections to the geothermal gradient or to the temperature data are usually performed sequentially, correcting first for the most recent perturbation (Bodmer and Rybach, 1983). This procedure is inaccurate since the different disturbances, for which correction is necessary, took place during overlapping episodes; they should therefore be treated simultaneously. A combined simultaneous calculation of the corrections is extremely arduous and the improvement of the results is in no relation to the increase of work. Furthermore it is generally impossible to obtain the requested parameters for detailed models.

The unknown proportion of conductive to convective heat transport represents a critical uncertainty in the correction of temperature data. Due to the lack of sufficient hydrogeological data, the convective heat flux can be only inaccurately estimated. In many cases the procedure is even inverted: the importance and the extent of water circulation systems is usually estimated by comparing the measured data after corrections (assuming pure conduction) with the expected temperature field. Large local anomalies in conjunction with pronounced variations in terrain altitude (i.e. strong relief of water table) suggest the occurrence of important convective processes. In attempt to account for the topographic, erosion and paleoclimatic effects on the temperature field, the corrections have been applied to the subsurface temperatures rather than to the geothermal gradients. The main reason for this lies in the HFD determination technique, the Bullard plot, which uses temperature values. Nowadays all calculations are performed by computers, even on PC's, using software developed for these purposes.

#### 5.4.1 Topographic correction

The topographic correction takes into account the distortion of the subsurface temperatures due to a relief surface. Most methods assume a constant temperature or a given temperature distribution at the earth's surface and a constant heat flow at a lower boundary of the model configuration. The distorted isotherms are corrected assuming an idealised planar earth's surface (reference plane). This reference plane intersects the actual topography at a location of the site investigated. It is important to note here that the topographic correction does not account for denudation but only for the change of shape of the earth's surface departing from an initially planar topography.

The topographic corrections in Switzerland were performed according to the method of Birch (1950). This method, which accounts for a 3-dimensional, time-dependent topography was chosen because it can treat the terrain with a maximum degree of precision at a sufficient radius around the site investigated. Correction techniques using stationary topography (i.e. Jeffreys, 1938) or 2-dimensional calculations are not accurate enough in areas such as the Alps. The numerical calculations, using the Birch's method, is performed by the computer code TOPO. This software is a strongly modified version of the one described by England (1976).

Digitizing the topography was unnecessary because of the prior existence of a digitised topography of Switzerland called RIMINI. RIMINI was compiled by the Swiss Military Department and contains in sequential order 331 segments, each covering a sheet of the official 1:25'000 topographic map of Switzerland. Each segment contains altitude data corresponding to a quadratic grid with a mesh width of 250 m (Züst 1977; Bodmer et al. 1979). More details about the use of TOPO, its input parameters, RIMINI and its features can be found in Bodmer (1982).

#### 5.4.2 Paleoclimatic correction

Temperature fluctuations at the earth's surface can penetrate to different depths, depending on their wavelength (i.e. duration). Daily temperature variations affect only the uppermost few tens of centimetres; seasonal variations penetrate up to a few tens of meters. Paleoclimatic changes, like glaciation periods, have affected the temperature field up to some thousands of meters depth so that

their effects are still disturbing a steady thermal "equilibrium". In order to correct for this paleoclimatic thermal disturbance a step model of temperature changes is chosen. The paleoclimatic temperature correction  $dT_{\text{paleo}}$  at a specified depth for a sequence of climatic events in the past can be obtained using the method after Birch (1948). To correct the temperature data properly also knowledge about present and past climatic parameters are needed. At particular the annual mean temperature at each site and the atmospheric lapse rate should be known and used according to Kappelmeyer and Haenel (1974). Further a paleoclimatic model for the site (i.e. for Switzerland) should be established. An attempt for this purpose have been made by Rellstab (1981, 1982). For applications of such paleoclimatic model in geothermics see Bodmer (1982), Schärli (1989), Kälin and Rybach (1990). Figure 4 shows the effect of temperature correction in the borehole St. Moritz, Figure 6 in that of Thun 1.

#### 5.4.3 Erosion correction

The topographic correction accounts only for the shape of the relief and its changes with time, but not for the removal of material. Erosion correction can be made using the methods developed by Carslaw and Jaeger (1959) and Von Herzen and Uyeda (1963). Some parameters utilised in order to compute this correction are usually not known or guessed in an inaccurate way. Especially the erosion history is full of uncertainties (erosion rate, glacial erosion, uplift or subsidence). This temperature data correction should be used only when all parameters needed are available and only for specific purposes. For the general use this correction is not advisable because it will introduce more uncertainty than correcting the data.

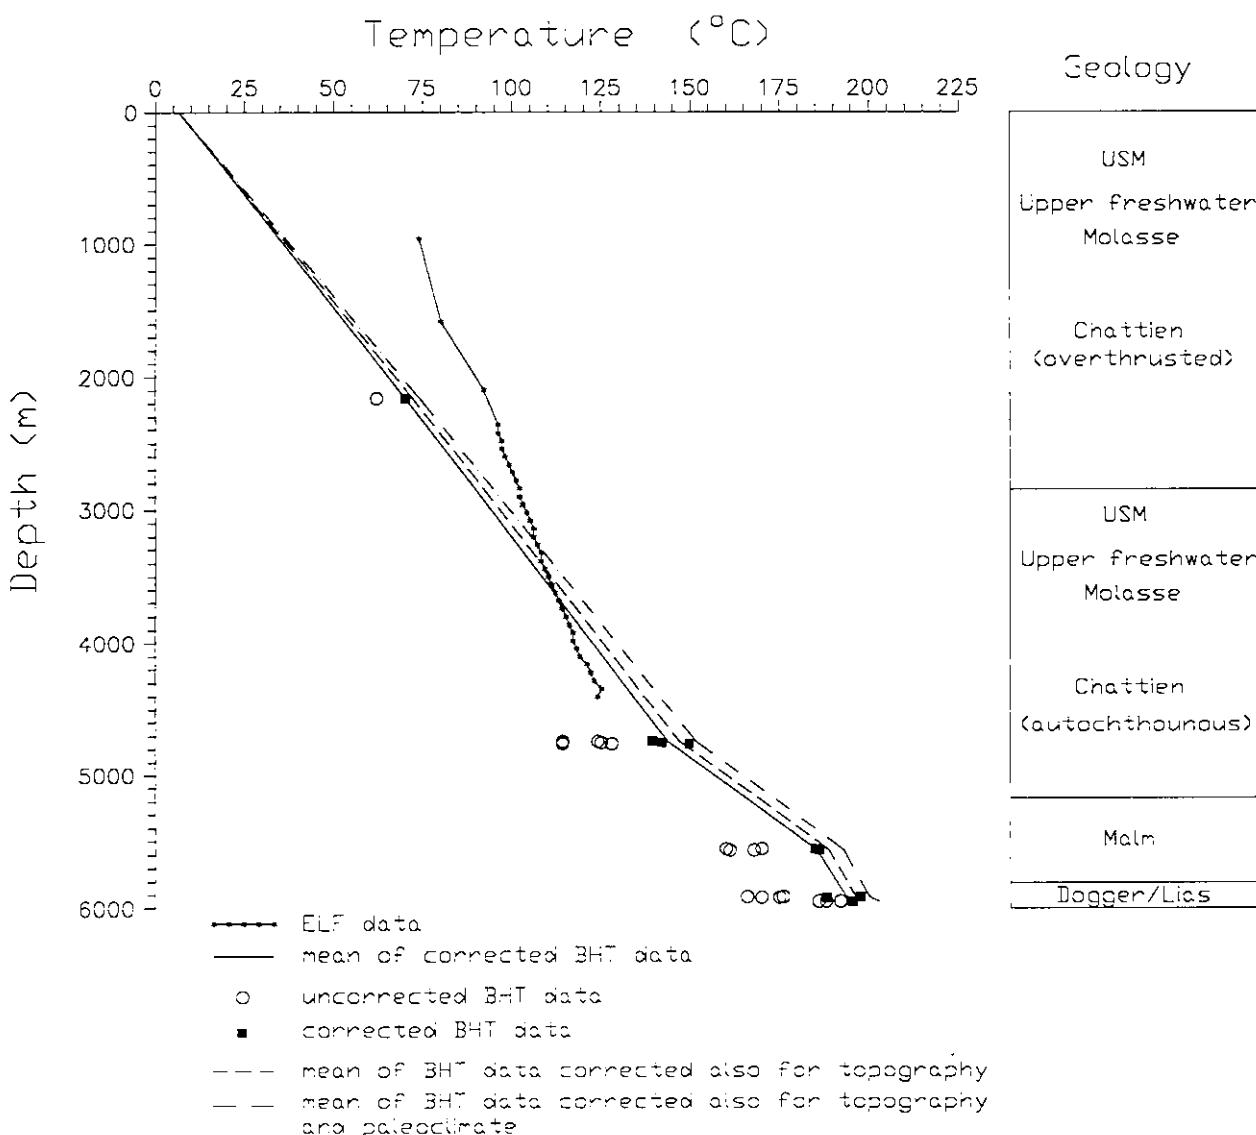

Figure 6. Temperature log with uncorrected and corrected BHT data from borehole Thun-1.

## 6. Geothermal Map of Switzerland

### 6.1 Mapping methods

The HFD determinations in Switzerland are unevenly distributed. Many interpolation methods are available to plot HFD contour lines on a map. Manual interpolations would introduce bias of unknown extent since the interpreter is usually influenced by physiographic units, geological boundaries, etc. A completely automatic map generation is, due the very unevenly scattered data points, not the best method either. Therefore a two-stage map contouring method was applied. In the first step an automatic contouring at intervals of  $10 \text{ mW m}^{-2}$  and a subsequent smoothing of the generated isolines were performed by computer. In the second step some the isolines produced only by numerical computations (i.e. where no data points are present) or that presented an "unrealistic" pattern were corrected or eliminated manually.

The Kriging method, which works on a statistical principle, is a widely used technique to interpolate geophysical data. However the HFD data points available are so unevenly distributed that in some regions computations led to numerical inconsistencies. For this reason a quadratic Inverse-Distance algorithm was chosen, where the weighting factor of a data point is inversely proportional to the distance of the other. For the interpolation also the choice of the appropriate mesh size is quite important. A wide mesh size, although appropriate in some areas with no data points, would lead to a loss of details in other regions. On the other hand a too fine mesh will produce much more details, due to the numerical computations, than what the existing data points should produce. For the Geothermal Map of Switzerland a mesh size of  $10 \times 10 \text{ km}$  was chosen. The interpolated region lies inside the Swiss co-ordinates 480.000/60.000 and 840.000/300.000, and consequently is composed of  $36 \times 24$  squares. The data points outside the mesh, until a distance of ca. 50 km from each country border extremities (i.e. inside Swiss co-ordinates 430.000/10.000 and 890.000/350.000, see Figure 2), were also taken in account for the interpolation. Most of the computation for contouring the HFD was done using a commercial available software called Tecplot™ (Amtec Eng., USA). All maps and figures were designed and plotted using AutoCAD® (Autodesk, USA).

As mentioned in Chapter 4 the reference sources for the HFD values used to construct the geothermal map of Switzerland are various. From many of them no exact information about the calculation procedures used is given or is possible to evaluate. Therefore in many cases very little is known about the quality and the uncertainty of the HFD determination. So it was not possible to introduce weighting factors for each data point according to its quality or presumed uncertainty.

The Geothermal Map of Switzerland 1 : 500'000 has been constructed on the basis of the complete data set given in Appendix I and II. In order to make this Swiss map compatible with other European HFD maps, only the topographic correction has been applied to the temperature data.

### 6.2 Results and Interpretation

The isolines of the Swiss HFD map cover the whole country. However in some region (e.g. in Valais, the south-western edge of the country and in Grisons, Eastern Alps) the isolines are dashed because their pattern is derived from very few and distant data points only (see Figure 8). New data points here could change their pattern in a very significant way. As illustrated in Figure 7, nearly half of the heat flow sites reach depths less than 500 m.

In Switzerland the mean regional HFD field decreases towards the south, from the Jura to the Central Alps and increases slightly again south of the Central Alps. The minimum lies approximately in the Central massifs where the earth's crust reaches its maximum thickness. Otherwise there is no or very little correlation with the surface geological features. However this can also be the result of the insufficient amount of data points which could outline geological or tectonic units. Several local anomalies can be attributed to deep groundwater circulating systems, in particular the pronounced positive anomaly in the northern part of Switzerland. The presence of the Permocarboniferous trough and intense fissuration allow deep warm waters to reach the surface or near surface formation (Schärli

and Rybach, 1991). The hot springs in the area of Schinznach, Baden and Zurzach are testimonies of these deep water circulation systems.

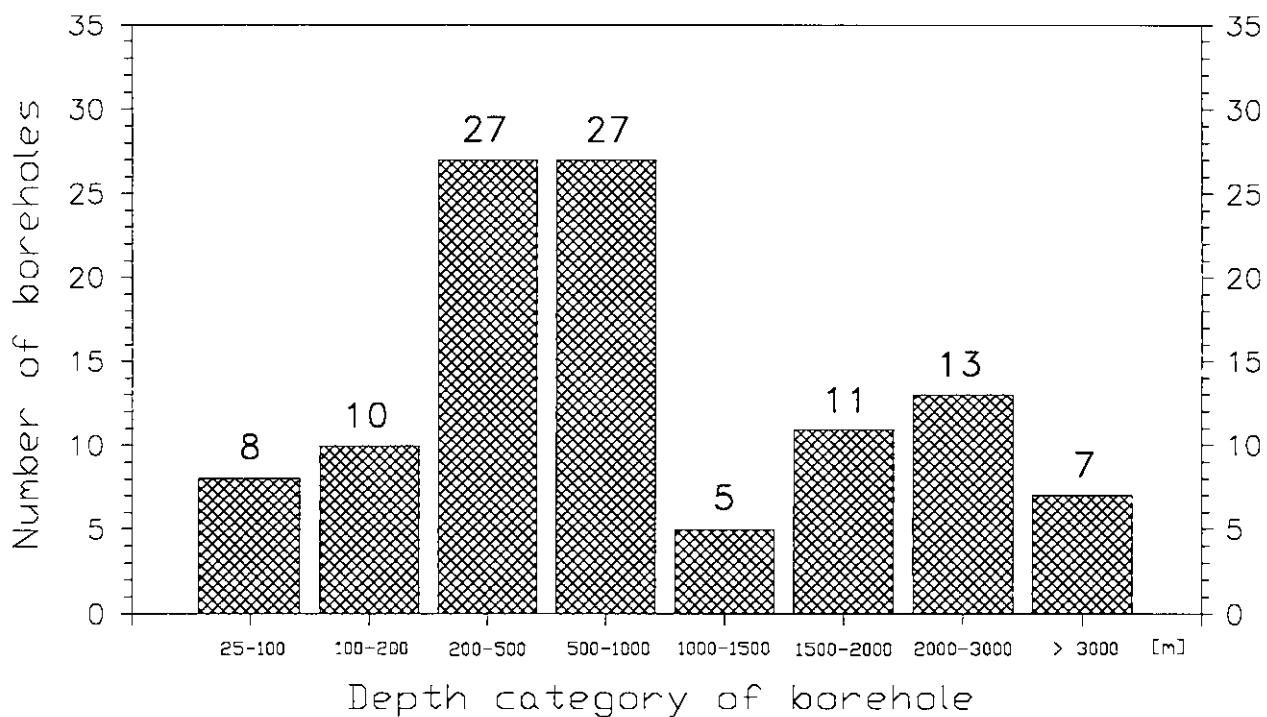

Figure 7. Depth distribution of Swiss boreholes used for HFD determinations.

In the 1985 edition of this geothermal map at the north-eastern edge of Switzerland a "dipole" like feature could be observed. This behaviour of the HFD field was due to bad quality data and inattentive line contouring. In fact this feature is created only by two data points; both HFD determinations there were calculated from very shallow boreholes: Brunnadern (60 m) and Gossau Silthang (31 m). For this new edition of the geothermic map it seemed reasonable not to include these data points for contouring the HFD field.

In addition to the HFD map three more maps are presented. They show the temperature field at 500 m, 1000 m and 2000 m depth. Due to the depth distribution of the boreholes and to the availability of data, these maps are not as complete as the HFD map. The sparsely distributed data points made the temperature values contouring by computer senseless. A manual attempt was made were the data allowed a "reasonable" interpolation.

## 7. Conclusions

More than ten years have passed since the first edition of the Geothermal Map of Switzerland was published. In the meantime, numerous new HFD determinations have approximately doubled the available database. The need of a revised edition of the geothermal map thus became evident. The database at the time of the first edition consisted of about 150 HFD values; nowadays about 340 HFD determinations, 150 in Switzerland and 190 in the surroundings, are available. Most of foreign HFD values were taken from the EGT HFD compilation. Except for the Quaternary layers and a few local disturbances the temperature-depth profiles in the Tertiary sediments of the Molasse basin are nearly linear. However many local and regional temperature disturbances due to water or gas movement can be detected within the Mesozoic sediments in the Molasse basin and along the Jura.

The methodology for calculating HFD values has not changed since the first geothermal map, but more powerful and user friendly software have reduced the amount of work needed. The usual corrections methods, which take into account the conditions at the earth's surface, were applied to the temperature data: the topographic and paleoclimatic correction. However for the HFD map at 1 : 500'000 only the topographic correction was applied according to common practice. The Swiss HFD map is therefore compatible and can be compared with the HFD maps of other European countries.

Many interpolation methods are available to plot HFD contour lines on a map. For establishing the new Swiss HFD map a special methodology proved to be suitable. Due to the distribution of the data points a quadratic Inverse-Distance algorithm was chosen, where the weighting factor of a data point is inversely proportional to the distance of the other (see chapter 6). In a first stage an automatic contouring at intervals of 10 mW m<sup>-2</sup> and a subsequent smoothing of the generated isolines were performed by computer. In a second stage some the isolines produced only by numerical computations (i.e. where no data points are present) or that presented an "unrealistic" pattern were corrected or eliminated manually. For the interpolation a mesh size of 10 x 10 km was chosen, inside the Swiss co-ordinates 480.000/60.000 and 840.000/300.000. The interpolated region is consequently composed of 36 x 24 squares. The data points outside the mesh, until a distance of ca. 50 km from each country extremities (i.e. inside Swiss co-ordinates 430.000/10.000 and 890.000/350.000), were also taken in account for the interpolation.

In Switzerland the mean regional HFD field decreases towards the south, from the Jura to the Central Alps and increases slightly again south of the Central Alps. The minimum lies approximately in the Central massifs where the earth's crust reaches its maximum thickness. Otherwise there is no or very little correlation with the surface geological features. Several local anomalies can be attributed to deep groundwater circulating systems, in particular the pronounced positive anomaly in the northern part of Switzerland. The presence of the Permocarboniferous trough and intense fissuration allow deep warm waters to reach the surface or surface near formation (Schärli and Rybach. 1991). The hot springs in the area of Schinznach, Baden and Zurzach are testimonies of these deep water circulation systems.

The HFD data density in Switzerland is among the highest in the world, nevertheless periodic updating on the basis of new data will be indispensable. More HFD determinations, especially in the Alpine area, are needed to delineate more precisely the terrestrial heat flow pattern.

## 8. Acknowledgements

Most HFD determinations have been performed in objects available for measurements ("opportunity boreholes", tunnels or shafts). In this regard the co-operation of numerous construction and oil/gas exploration companies, consulting bureaux and various cantonal and communal authorities must be mentioned. We would also thank St. Eugster (Zürich) for calculating about 20 new HFD values and for his efforts in using new methods for the representation of a new edition of the geothermal map.
